Abstract

Background Postoperative ambulation is encouraged to promote timely recovery but is rarely monitored objectively or examined as a predictor of clinical outcomes, despite growing availability of wearable devices that allow passive quantification and remote real-time monitoring of the number of steps taken during recovery.

Purpose To determine whether the number of steps taken during inpatient recovery predicts 30- and 60-day readmission risk after metastatic cancer surgery.

Methods Patients diagnosed with metastatic peritoneal cancer and scheduled for surgical resection were enrolled in this observational cohort study at their preoperative clinic visit. Fitbits were placed on patients’ wrists upon transfer from the ICU following surgery and worn for the duration of their inpatient stay. Information about hospital readmission was extracted from electronic medical records.

Results Seventy-one patients participated in the study (mean age = 57.14, range = 31–80 years; 42% female; 51% diagnosed with appendiceal cancer). Mean steps per day were calculated for each participant over the entire inpatient recovery period (mean stay = 12.12 days, 4–37 days). Readmission within 30 and 60 days was medically indicated for 34% and 39% of patients, respectively. After statistically adjusting for age, body mass index, comorbidity, and length of postoperative stay, higher mean steps per day predicted lower 30-day and 60-day readmission risk.

Conclusions Higher Fitbit step counts during inpatient recovery predicted lower risk of 30- and 60-day readmission after surgery for metastatic peritoneal cancer. Results suggest that passively monitoring perioperative ambulation may identify patients at risk for readmission and highlight opportunities for behavioral intervention.

Keywords Cancer • Surgical oncology • Physical activity • Readmission

Introduction

Readmission is common after complex cancer surgeries, with 15%–50% of patients readmitted within 30 days of discharge following abdominal cancer resections [1,2,3]. Preventable readmissions are associated with increased health care costs, poor long-term outcomes including early mortality, and patient and family stress and suffering. The Affordable Care Act highlighted readmission as a target for quality improvement by establishing the Hospital Readmissions Reduction Program, which penalizes hospitals for excess 30-day readmission rates [4]. Prior analyses have identified demographic and medical predictors of 30- and 60-day readmission risk such as older age, comorbidity, and length of hospital stay [5,6], but the role of patient-centered behavioral processes such as physical activity has received relatively little research attention. Identifying modifiable behavioral factors predictive of readmission could highlight opportunities for...
behavioral intervention and empower patients to take a more active role in their recovery.

Early ambulation is encouraged after surgery and is a key component of Enhanced Recovery After Surgery multimodal interventions [7], but postoperative ambulation is rarely monitored systematically as part of clinical care or examined as a predictor of important clinical outcomes such as readmission. The recent emergence and growing popularity of commercially available, low cost, reliable wearable devices (e.g., “Fitbits”) permit simple, objective, and continuous quantification of physical activity and remote real-time monitoring of patient ambulation, but whether these passively sensed data can predict subsequent clinically important outcomes remains unclear. Previous research with a cardiac surgery population suggests that higher numbers of Fitbit-assessed steps during postoperative hospitalization are associated with shorter length of inpatient stay [8]. Lower accelerometer-assessed step counts have also been associated with higher patient-reported 1 year readmission risk after cardiac surgery [9] and higher 30-day readmission in older hospitalized medical patients [10].

The goal of this study was to determine whether mean Fitbit-assessed daily steps taken during inpatient recovery predicts 30- and 60-day readmission risk after metastatic peritoneal cancer surgery.

Methods

Participants

A convenience sample of 71 patients with Stage IV peritoneal carcinomatosis who underwent hyperthermic intraperitoneal chemotherapy with cytoreductive surgery (HIPEC + CS) at a large academic center between July 2014 and October 2016 participated in this observational cohort study. Patients were referred to the study by their surgical oncologist at the time of consent to surgery. At this time, written informed consent for the study was obtained. This study was approved by the University of Pittsburgh’s Institutional Review Board.

Measures

Fitbit steps

Fitbit Flex or Charge devices were placed on participants’ nondominant wrists at the time of their transfer from the ICU to the postoperative recovery floor (typically postoperative day 2). Participants were instructed to wear the device at all times, except during charging (1–2 hours every 5–8 days). Devices were collected on the day of discharge by research staff and reused across participants. Days with incomplete step count data (i.e., the day of placement and the day of discharge) were omitted from analyses. Mean Fitbit step count was computed by averaging the daily step count across all inpatient days for each participant.

Readmission

Information about readmissions within 30- and 60-days postdischarge was extracted from the medical record, including inpatient, outpatient, and telephone contact notes. Readmission was defined as admission to any hospital within 30 or 60 days of index discharge. Patients who died within 30 days of discharge or who did not have postoperative records reflecting the entire postoperative window were not included in analyses.

Covariates

Age, sex, body mass index, diagnosis, preoperative American Society of Anesthesiologists (ASA) physical status, age-adjusted Charlson comorbidity index (CCI), and postoperative length of stay were extracted from the electronic medical record and examined as potential covariates. Covariates were selected on the basis of previously published associations with readmission risk and/or postoperative ambulation (i.e., age, body mass index, length of stay, comorbidities; [3, 9, 10]). In exploratory analyses, we also considered the role of preoperative activity level, which was assessed prior to surgery using the following question from the National Health Interview Survey: “Outside of your normal work or daily responsibilities, how often do you engage in exercise that at least moderately increases your breathing and heart rate, and makes you sweat, for at least 20 min (such as brisk walking, cycling, swimming, jogging, aerobic dance, stair climbing, rowing, basketball, racquetball, vigorous yard work (gardening), etc.)?” [11]. Response options ranged from 1 to 4 and included seldom or never, 1–2, 3–4, or 5 or more times per week (mean = 2.53, standard deviation = 0.98).

Statistical Analysis

Data analyses were conducted using SPSS version 24. Descriptive statistics were first performed to characterize the sample and the distribution and frequency of variables. Variables were categorized for analyses using the following groups: sex (male vs. female), diagnosis (appendiceal cancer vs. other), ASA status (2-mild systemic disease vs. 3-severe systemic disease or 4-severe systemic disease that is a constant threat to life), and CCI (6–8 vs. 9 or higher).

Of the 71 participants, 10 were missing Fitbit data due to: device failures (n = 5, due to three malfunctioning Fitbit Flex devices), short postoperative inpatient stays

in need of additional monitoring or intervention prior to discharge [12]. Results are consistent with previous research in general medicine and cardiac patients indicating associations between accelerometer-assessed steps and readmission risk (e.g., [9,10]). To our knowledge, this is the first study to link Fitbit wristband-assessed step counts to readmission in any clinical sample as well as the first to examine associations between steps and readmission risk after cancer surgery.

Although demographic and clinical data (e.g., age, number of admissions in the past year) have proven useful in identifying patients at high risk for readmission [5,6], these risk stratification algorithms suffer from two important limitations. First, demographic and clinical variables are generally not modifiable so provide limited guidance for interventions aimed at reducing preventable readmissions. Conversely, postoperative mobility can be modified via behavioral interventions [13], which may hold promise in optimizing recovery and postoperative outcomes. These behavioral interventions could be targeted to populations known to be at elevated risk for readmission, such as older patients. Second, administrative algorithms typically use data only available upon hospital discharge (e.g., length of stay, lab values at discharge), permitting minimal opportunities to monitor and support at-risk patients during their inpatient recovery. Fitbit steps can be tracked throughout the inpatient stay and may allow for earlier identification of at-risk patients.

Several limitations warrant mention. First, our sample was relatively small and medically homogeneous, and results should be replicated in larger and more heterogeneous clinical populations. Second, although we found similar mean daily Fitbit postoperative step counts when compared to previous inpatient accelerometer studies (mean = 1,158 steps/day, ref. [14]) and Fitbit step counts are generally accurate [15], the reliability and validity of Fitbit step counts has not yet been established for slow or assisted walking and may have underestimated steps for patients moving slowly or with assistance [16].

We also used two different Fitbit devices, the Flex (worn by 54% of participants) and the Charge (worn by 46%), that may have differed in their step counts; note that adjusting for type of device did not affect results (data not shown). Third, given the wide range in length of inpatient stay between patients, we elected to focus on mean steps per inpatient day to capture all available data on ambulation from ICU transfer to hospital discharge, but within-person variability in step counts during inpatient recovery (e.g., slope) should also be examined in future research. There may also be critical periods of recovery (e.g., the first days after surgery or the last days before discharge home) during which individual differences in activity are particularly important. Fourth, patients in our study experienced higher readmission rates than those reported in other samples undergoing cytoreductive surgery with hyperthermic intraperitoneal chemotherapy (e.g., 15% in ref. [1]), suggesting that patients treated at our tertiary academic medical center may be more sick or frail than surgical oncology samples elsewhere. Finally, we assessed steps only during inpatient recovery on the postoperative recovery floor and did not monitor ambulation prior to surgery or after discharge.

Future directions for this area of research include extending assessment of ambulation to include the 60 days after discharge, as steps taken once a patient returns home from the hospital may be even more critical than inpatient steps in predicting readmission risk. Assessment of steps taken prior to surgery reflecting individual differences in baseline activity level or fitness level may further account for additional variance in readmission risk. Collecting data on reasons for lack of ambulation may also inform the design and delivery of interventions, as reasons could include symptom burden such as uncontrolled pain or fatigue, disruption of typical routines and environment while in the hospital, anxiety about falling or irritating surgical incisions, or beliefs about whether activity will help or hinder healing.

Passively sensed data on sedentary behavior may account for additional variance over and above the predictive utility of step counts [17]. Testing whether behavioral interventions aimed at increasing perioperative ambulation influence readmission and other clinical outcomes would shed light on whether activity has a causal influence on readmission. Finally, future research should extend this work to other clinical populations to determine whether findings generalize to predict readmission in the context of other chronic or acute health conditions.

In conclusion, higher postoperative mean daily step counts significantly predicted lower risk of readmission after complex surgery for metastatic peritoneal cancer. After adjustment for demographic and medical covariates, taking 100 additional steps per inpatient recovery day was associated with 17% lower risk of 30-day readmission and 18% lower risk of 60-day readmission. Results highlight the potential of commercial activity monitors to improve postoperative care by identifying patients in need of additional monitoring or intervention after cancer surgery.
